**3-D Seismic Evaluation of Fault Control on
Quaternary Subsidence Patterns, Rates, and Related
Surface Morphology in Southeastern Louisiana**

**Approved by
Supervising Committee:**

This thesis is dedicated to my grandmother, Eloyese, who is a constant source of love and encouragement; to my parents, Terry and Kathy, who have sacrificed much to allow me to succeed; and to my sister, Laramie, who has been a help and comfort during this process. This thesis is also dedicated to my extended family and friends, who are too many to list. Thank you all for the prayers and encouraging words, which have made all the difference.

Acknowledgments

The author wishes to express her sincere gratitude to Dr. David Mohrig for his valuable support and accurate supervision of this thesis and through-out the past two years at U.T., and to thank Drs. William L. Fisher and Ronald J. Steel for serving on this thesis committee.

Also, I would like to thank Dr. Elizabeth J. Catlos and Mr. Mark Falk for their encouragement, advice, and guidance in the preparation of this document, as well as Mr. Aymeric-Pierre B. Peyret for many hours of L^AT_EX-formatting assistance. Further, I would like to thank the faculty and staff of the Jackson School of Geosciences for their guidance, especially Mr. Thomas E. Hess for many hours of help with seismic processing. Additional thanks to Mr. Jeffrey Nittrouer for miscellaneous help and advice during my career at U.T.

This project was made possible by: Western Geco[®], OpendTect[®], Seismic Micro-Technology[®], the National Center for Earth-surface Dynamics (funded by the Office of Integrative Activities, N.S.F., under agreement Number EAR-0120914), and ConocoPhillips Co.

Finally, I would like to thank God for the opportunity to work with an amazing dataset and so many talented individuals.

3-D Seismic Evaluation of Fault Control on Quaternary Subsidence Patterns, Rates, and Related Surface Morphology in Southeastern Louisiana

Terra Jane George, MS. GeoSci.
The University of Texas at Austin, 2008

Supervisor: David Mohrig

Throughout the past century, the Louisiana coastline has been deteriorating at an alarming rate. Fault induced subsidence has been suggested to be one of the likely drivers of this land loss. I directly addressed the control of faulting on Quaternary delta subsidence using subsurface architectural data. I carried out a systematic process for evaluating fault movement on individual faults in the subsurface by using an industry grade 3-D seismic survey to evaluate the interaction of complex fault patterns and shallow substrate ($< 1s$ or $1,000m$). Using amplitude data, as well as a coherency algorithm, horizons and faults were mapped in $\sim 1400km^2$ of data in southeastern Louisiana. Measurements of fault displacement were obtained by determining time offset of

synchronous horizons. Down-to-the-basin and counter-regional growth faulting was observed. Both styles of faulting are associated with movement of Jurassic-age salt deposits and display measurable offset at depths as shallow as $\sim .450s$ (roughly $380m$). Fault displacements increase roughly linearly with burial depth. The displacement data together with well-log data provide a tentative Quaternary rate for the normal faulting of $0.1mm \cdot yr^{-1}$ to $1mm \cdot yr^{-1}$.

I have assessed the possible control of subsurface faulting on surface topography using co-registered maps of fault traces and orthophoto quadrangles. This analysis has revealed a number of instances where faulting affects modern surface morphology. Often, the up-thrown sides of growth faults are capped by marshland, whereas the downthrown blocks are drowned by $\sim .7m$ of surface water (Snedden et al., 2007). Further, the influence of faulting extends to the modern planform of the lower Mississippi River, as data indicate that growth faults control the position of a major bend near the river's outlet.

Chapter 1

Introduction

In 2005, Hurricanes Katrina and Rita brought national attention to a long-standing problem in southern Louisiana. Wetlands and barrier islands, critical for protection from storm surges, have been inundated by seawater due to rapid subsidence during the 20th century (Gagliano et al. (1981); Turner and Cahoon (1988); Morton et al. (2005)). While this issue has been documented for decades by scientists and engineers (Morgan and Larimore (1957); Gagliano et al. (1981); Williams et al. (1992); Beall et al. (2005); Morton et al. (2005)), it has recently drawn the attention of political leaders due to the region's population and prominence as a major economic center for a variety of industries and commerce, including fisheries, petroleum production, and natural gas distribution (Turner and Cahoon (1988); Gagliano (2005b); Morton et al. (2005)). Further coastal deterioration increasingly subjects Louisiana to catastrophic flood events that endanger lives, in addition to the nation's economy; therefore, an understanding of the driving forces behind subsidence, and measures necessary to prevent further degradation of wetlands and barrier islands are critically important.

A considerable number of theories have been proposed concerning the fundamental causes of subsidence on the Mississippi delta (Törnqvist et al., 2006), including natural compaction of sediments (Meckel et al. (2006); Meckel et al. (2005); Törnqvist et al. (2008)), removal of hydrocarbons and formation water (Morton et al. (2001); Morton et al. (2005)) and structural deformation with associated faulting (Gagliano (2005c); Dokka et al. (2006); Dokka (2006)), leading to significant debate as to the primary drivers of land loss. Many of these studies have utilized surface measurements (GPS elevation data) and shallow sediment cores; however few have incorporated subsurface architectural data to evaluate the causes of land subsidence and coastal deterioration. This study does so by using a recently collected, 3-D seismic volume from greater Breton Sound, Louisiana. With this data I have been able to identify subsurface features, such as faults and mobile substrate (salt), which allow me to better determine the control of structural deformation and growth faulting on the patterns of delta-top subsidence.

Chapter 2

Geologic Setting

In order to comprehend how modern subsidence in coastal Louisiana is driven, it is necessary to understand the geologic history and framework of the greater Gulf of Mexico basin. Evolution of the gulf influences the contemporary processes of sedimentation and growth faulting that impact southern Louisiana today.

2.1 Mesozoic

Initial formation of the Gulf of Mexico basin is tied to early Mesozoic crustal extension and break up of the super continent, Pangaea. This rifting took place near the modern-day southern margin of the North American Plate (Dunbar and Sawyer (1988); Salvador (1991a)). By the Early Jurassic, several developing grabens were flooded with seawater, creating a restricted seaway that ran all of the way across Mexico and was connected to the Pacific Ocean. An arid climate led to the development of a hyper-saline environment in this seaway and to the widespread accumulation of salt deposits (Humphris (1978); Buffler et al.

(1980); Salvador (1991a); Diegel et al. (1995)). Roughly 1,500m of Jurassic-age Louann Salt was deposited during this time (Andrews (1960); Maione (2001)).

Continued rifting resulted in emplacement of oceanic crust by the Late Jurassic, marking the completion of Pangaea break up. Thermally driven subsidence of the Gulf of Mexico basin associated with the cooling oceanic crust, dominated basin development until the Cretaceous when sediment loading became the predominant subsidence mechanism (Salvador, 1991a).

The Early Cretaceous Gulf of Mexico basin experienced increased tectonic stability. Terrigenous sediments continued to be deposited into the basin, leading to mobilization of the Jurassic-age salt deposits and associated development of growth faulting (Sohl et al. (1991); Salvador (1991a); Yurewicz et al. (1993)).

A marine transgression during the Cretaceous allowed the Atlantic Ocean to finally link to the waters of the gulf. This transgression, combined with a greenhouse climate, led to the formation of many carbonate reefs throughout the basin and created a well-defined shelf margin which prograded into the basin over time (Salvador (1991a); Yurewicz et al. (1993)). The Mississippi Embayment, future site of the greater Mississippi delta, experienced varying episodes of clastic and carbonate sedimentation until the late Cretaceous when the Laramide Orogeny produced a tremendous influx of clastic sediment to the northern gulf. This sedimentation further drove salt movement and growth faulting and salt movement (Salvador, 1991a).

2.2 Early Cenozoic

The Early Cenozoic Gulf of Mexico continued to experience the delivery of large volumes of Laramide-derived terrigenous sediment to the basin. Siliciclastic sedimentation was most pronounced during the Paleocene and Early Eocene,

causing the shelf margin to prograde 240 to 290km from its inherited Cretaceous position (Salvador (1991a); Galloway et al. (2000)). An avenue of terrigenous sediments deposited in what is now western Mississippi, southeastern Arkansas, and northwestern Louisiana is cited as evidence for establishment of the lower Mississippi River system by the Late Paleocene/Early Eocene (Galloway et al., 2000).

Tectonic activity in the hinterland kept rates of sediment delivery to the basin relatively high until the Late Oligocene when the region experienced a long term systems-tract retreat which shrank the Mississippi Delta and allowed coastal and shelfal deposits to be reworked by longshore drift. (Salvador (1991a); Galloway et al. (2000)).

Increased arrival of sediments in the early Miocene renewed the progradation of the Mississippi River Delta, which grew larger than its Oligocene predecessor. Additional shore-zone systems were created, but were affected by sub-regional, geologically ephemeral episodes of hyper-subsidence and collapse from growth faulting and salt movement (Galloway et al., 2000). By the Late Miocene/Early Pliocene, the Mississippi River had become the principle conduit for sediment off of the craton. Nearly 4,000m of terrigenous clastics were deposited over 4 million years during the Pliocene, the highest sedimentation rate observed for the Cenozoic. This large volume of fluvial-deltaic sediments prograded the shoreline and continued activating growth faulting and movement of Jurassic-age salt (Salvador, 1991a).

2.3 Quaternary

Pleistocene climate changes dramatically altered the sedimentation patterns in the gulf. The last major continental glaciation lowered mean sea level by $\sim 150m$ relative to today, exposing large areas of the northern shelf. Previously

deposited shelf sediments were eroded and entrenched by channels traversing this exposed surface. The re-eroded sediment was deposited at the shelf edge and on the continental slope, off the shore of modern-day Louisiana (Fisk (1944); McFarlan (1961); Salvador (1991a); Galloway et al. (2000), Kulp et al. (2002)) and the contemporary Mississippi Delta.

During this time, nearly 3,800m of sediments were deposited, triggering additional gravity slumping, growth faulting, and salt movement. As the Jurassic-aged salt mobilized, it further influenced the distribution and deposition of clastic sediments. These features are still active processes in the contemporary basin (Salvador, 1991a).

Another affect of salt movement and growth faulting is the occurrence of mini-basins. These basins, which are found between allochthonous salt diapirs, have some of the highest subsidence rates recorded, and are found throughout the Quaternary (Worrall and Snelson (1989); Salvador (1991a); Jackson et al. (1994b) or Jackson et al. (1994a); Schuster (1995); Gras et al. (1998)). These salt bodies, mobilized in the early Cenozoic, have moved horizontally through the basin as much as 150km from their original site of deposition (Salvador, 1991a).

The Holocene history of the Gulf of Mexico is characterized by sea-level rise from deglaciation. The Mississippi River acted as a conduit for delivering large volumes of glacial meltwater to the basin (Ruddiman and Wright (1987); Salvador (1991a); Kulp et al. (2002)). Incised areas created during the previous sea-level fall were flooded, and sediments began to fill these canyons (Fisk (1944); Fisk et al. (1954); Coleman et al. (1991); Kulp et al. (2002)). Sedimentation associated with the Mississippi River substantially prograded its delta, creating surface features such as barrier islands, wetlands, lagoons, beaches, and dunes that are still seen today (Fisk (1944); Morgan and Larimore (1957);

Salvador (1991a); Williams et al. (1992); Kulp et al. (2002)). Syn-depositional growth faulting and salt movement continued as a result of sediment loading and still persists today (Coleman et al. (1991); Gagliano (2005a); Dokka et al. (2006)).

Landforms, which were created by an influx of Quaternary sediment, (Coleman et al. (1991); Salvador (1991a); Williams et al. (1992)) are maintained by sediment supplied predominately by the Mississippi River (Fisk (1944); Coleman (1988); Coleman et al. (1991); Williams et al. (1992); Kulp et al. (2002)). The continued addition of new sediment is necessary to counteract land-surface subsidence (Penland *et al.*, 1992) associated with natural compaction (Meckel et al. (2007); Törnqvist et al. (2008)), salt movement, and growth faulting (Worrall and Snelson (1989); Salvador (1991a), Diegel et al. (1995)). Traditionally, flood events and avulsions have provided the sediment to replenish subsiding coastal landforms such as barrier islands (Fisk (1944); Coleman (1988); Boyd et al. (1989); Penland et al. (1988); Williams et al. (1992)). Avulsions of small distributaries and of the larger channel have occurred throughout the history of the river, with at least three events taking place on the main channel during the Holocene (Aslan et al., 2005). It has been estimated that avulsions of the Mississippi River have happened roughly every 1,000 years during the Holocene, and it has further been suggested that the river was experiencing an incipient avulsion into the mid-twentieth century that was averted by construction of the Old River Control Structure (Fisk et al. (1954); Aslan et al. (2005)).

2.4 Human Influence on Delta

Various other engineering efforts have been implemented on the river under the authority of the Mississippi River and Tributaries Project (MR&T) (Biedenharn et al., 2000). Artificial features such as meander cutoffs, levees, and river-

training dikes were constructed to steady the main channel and its distributaries (Biedenharn et al., 2000), reducing the natural process of avulsion which is critical for maintaining subsiding coastal landforms (Fisk et al. (1954); Coleman (1988); Williams et al. (1992); Beall et al. (2005)). The stabilization of the Mississippi River, while intended to quell flooding events, has resulted in the efficient transport of sediment all of the way to the shelf edge. Because of this new depositional regime, coastal features that rely on sediment to overcome the effects of subsidence are steadily drowning (Williams et al. (1992); Day et al. (2007)).

Reduction of wetlands, barrier islands, and other coastal landforms has been occurring at rates as high as $100\text{km}^2 \cdot \text{yr}^{-1}$ (Gagliano et al. (1981); USGS (2003); Day et al. (2007)). It is estimated that from 1932-2000, Louisiana lost approximately $3,050\text{km}^2$ of land, while an additional $1,100\text{km}^2$ is projected to be inundated during the next 50 years (USGS, 2003). This loss is significant because these shore-zone features provide essential protection for Louisiana's wide variety of commerce and its increasing population from damaging, high-energy waves and storm surges (Williams et al. (1992); Stone et al. (2004); Day et al. (2007); Törnqvist et al. (2008)). The need for the protection was quite apparent in 2005 when Hurricanes Katrina and Rita pummeled the coast, creating wide-spread destruction and loss of life.

Overall, the Cenozoic history of the Gulf of Mexico, particularly in the Mississippi Delta region, has been marked by high sedimentation rates, which in turn have driven growth faulting and Jurassic-age salt movement. These processes, coupled with natural compaction, have led to well documented areas of hyper-subsidence. Large volumes of sediment, historically deposited on the coast through processes such as avulsion and regional-scale flooding, minimized the effects of subsidence and maintained shore-zone features critical for

protection against storm surges. Artificial stabilization of the Mississippi River has limited its ability to effectively disperse sediments, allowing wetlands and barrier islands to succumb to the effects of on-going subsidence.

It is evident that both human interaction and natural geologic phenomena are influencing the modern surface morphology of coastal Louisiana. This study seeks to delineate the location, frequency, and severity of subsurface features, namely faults, using industry seismic data with well control. A more complete knowledge of fault controlled subsidence is necessary input data for any program designed to restore wetlands.

Chapter 3

Previous Work

For decades, researchers have attempted to quantify the drivers of subsidence in Mississippi River delta and to understand their influences on wetland loss in coastal Louisiana. Subsidence is most often measured by radiocarbon dating buried peat deposits or by recording vertical displacement of benchmarks on surface structures (Morton et al. (2001); Gagliano (2005a); Gagliano (2005c); Gagliano (2005b); Dokka et al. (2006); Törnqvist et al. (2008)). Other methods used to obtain subsidence measurements include: satellites, tide gage records, movement of historical and archeological features, and total area of land loss (Gagliano (2005a); Gagliano (2005c); Gagliano (2005b)). Some 2D seismic lines have been used to identify faulting related subsidence (Lopez et al., 1997), but no comprehensive studies have been completed using modern-day 3-D seismic data.

3.1 Measured Subsidence Rates

Subsidence rates in coastal Louisiana have been studied by many researchers over roughly the past century. The results of several of those studies are pre-

sented in Table 3.1 (located at the end of the chapter). A variety of methods have been employed to estimate subsidence rates, yielding values that range from $0 - 30mm \cdot yr^{-1}$.

The approaches taken in previous work are problematic because of heavy reliance on surface or very shallow subsurface data to make claims about deep seated subsurface processes. Few workers have incorporated any seismic data (Lopez et al., 1997) into their interpretations creating a situation with vast amounts of generated values, but little understanding about the subsurface components that influence those values. This problem is reflected not only in the table, but in many of the controversies that have been stirred as political leaders look to scientific studies to evaluate proposed solutions for combating the subsiding Louisiana coastline.

3.2 Proposed Drivers of Subsidence

Many different explanations have been offered to account for the highly variable subsidence rates measured in southern Louisiana. Three of the most commonly cited explanations for this subsidence are: 1) natural compaction of shallowly buried sediments; 2) compaction via pore-space reduction associated with withdrawal of groundwater and hydrocarbons (oil and natural gas); and 3) faulting. Each of these causes has been the subject of multiple papers, special reports, and in some cases, political hearings.

3.2.1 Subsidence from Natural Compaction

Shallow compaction refers to the thinning of a column of sediment due to natural mechanical reorganization of grains that leads to a reduction in porosity (Meckel et al., 2006). This process increases the bulk density of the sedimentary deposit and causes an overall decrease in its volume. It has been proposed

that shallow compaction is the primary force causing subsidence in southeastern Louisiana (Törnqvist et al., 2008).

Subsidence attributed to natural compaction has been measured at rates up to $5mm \cdot yr^{-1}$ using C-14 dating of buried peat deposits (Törnqvist et al., 2008) and $2.2mm \cdot yr^{-1}$ using stochastic numerical models (Meckel et al., 2006). Morton et al. (2005) and Meckel et al. (2006) provide values for 104 measurements of subsidence using buried peats. The average subsidence rate for this data set is $1.4mm \cdot yr^{-1}$. This rate is associated with a time averaging interval of 100+ to 1000 years and should be thought of as a long-term value. Subsidence rates associated with only natural compaction are significantly less than the unusually high rates recorded in some places (Table 3.1). Because the measurements are taken near the surface, the shallow substrate methods often record total subsidence acting upon an area, limiting the ability to independently evaluate this component.

3.2.2 Subsidence from Removal of Subsurface Fluids

Southern Louisiana has long been a site of substantial hydrocarbon and groundwater extraction since the 1940s. Observed wetland decline around well sites has created suspicion that subsidence is induced as subsurface fluids are extracted (Morton et al., 2001). Studies conducted on benchmarks and sediment cores within multiple production areas have shown subsidence rates as high as roughly $30mm \cdot yr^{-1}$ (Morton et al. (2001); Table 3.1). This high rate suggests accelerated subsidence in areas where subsurface liquids are being pumped out. However, use of shallow borings and benchmarks alone does not allow the subsurface fluid removal component to be tested independently, as these methods of measurement record total subsidence at or near the surface.

3.2.3 Subsidence from Faulting

As previously highlighted in the geologic history section, large volumes of sediment have been deposited in the Mississippi Delta, triggering the movement of the buried, Jurassic Louann Salt. Sediment loading and salt movement has produced a vast network of growth faults. Since the 1970s many of these faults have been mapped in coastal Louisiana (Hickey and Sabate (1972); Lopez et al. (1997)). The presence of these features has led several researchers to propose that movement along growth faults exerts a primary control on subsidence rates (Lopez et al. (1997); Gagliano et al. (2003); Gagliano (2005a); Gagliano (2005c); Gagliano (2005b); Dokka (2006); Dokka et al. (2006)).

The term “growth fault” refers to a style of normal faulting that occurs syn-depositionally. Because fault movement is concurrent with deposition, the downthrown block (hanging wall) is characteristically thicker than the footwall (Suppe, 1985). The listric shape of these faults creates characteristic “rollover” and “depression” features which are sites of enhanced subsidence (figure 3.1). A regional growth fault is oriented with the hanging wall situated towards the basin, while the hanging wall of the counter-regional fault is situated away from the basin (figure 3.2). Counter-regional faults, though they have a similar geometry as regional growth faults, are specifically associated with salt movement.

In southern Louisiana growth faults have generally been detected using aerial photographs, offsets on structures, previously published fault maps, personal interviews, geomorphic alterations, and in some cases, 15 to 30 year old 2-D seismic data consisting of only a few lines (Hickey and Sabate (1972); Lopez et al. (1997); Gagliano et al. (2003); Gagliano (2005b); Dokka et al. (2006)). These data types are pieced together to locate faults in order for subsidence measurements to be obtained. Measurements of fault related subsidence are

Figure 3.1: Schematic diagram of growth fault, modified after Gagliano (2005b). Subsidence occurs along the depression of a growth fault.

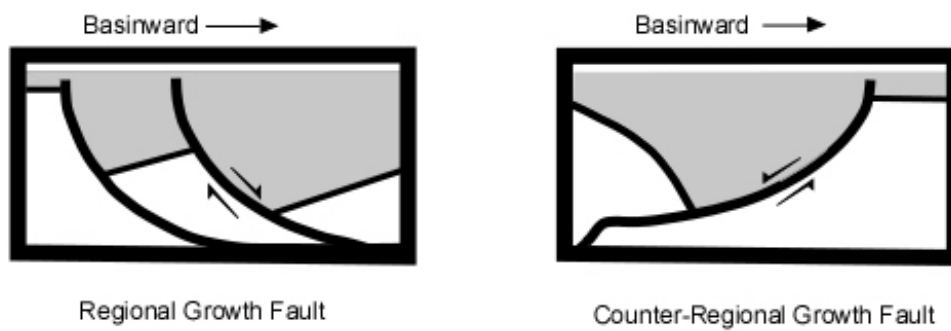

Figure 3.2: Regional growth faults are oriented slipping towards the basin, while counter-regional growth faults slip away from the basin. Modified after Schuster (1995)

frequently made by using vertical displacement on benchmarks and tide gauge records (Gagliano (2005b); Dokka (2006); Dokka et al. (2006)). In some studies, displacements of structures such as roads, buildings, railroads, and bridges have also been utilized (Lopez et al. (1997); Gagliano et al. (2003)). Many different combinations of methods to locate faults and measure displacement have been used, yielding a variety of subsidence rates and in turn, many proposed theories to account for those rates.

3.2.3.1 Fault Related Studies

One of the first studies attempting to quantify growth fault movement in southeastern Louisiana was completed near Lake Pontchartrain (figure 3.3) (Lopez et al., 1997). Using shallow 2D seismic provided by the USGS, two faults were identified in three lines. During a six-year period, offsets on railroad bridges which crossed the faults were recorded. This study reports a range in vertical displacement rates across faults of $2.5mm \cdot yr^{-1}$ to $10mm \cdot yr^{-1}$ (Lopez et al., 1997). These relatively instantaneous or “modern” rates for normal fault displacement are substantially greater than other fault displacement rates collected in the Lake Pontchartrain area. Averaged over 1,000,000+ years, these reported long-term or “geologic” rates range between $0.003mm \cdot yr^{-1}$ to $0.064mm \cdot yr^{-1}$ (Lopez et al., 1997). Lopez et al. (1997) suggested that this discrepancy in rates is a consequence of longer term geologic rates including both times of fault motion and times of quiescence, while the “modern” rates include only active fault displacement.

In 2004, the U.S. Department of Commerce, along with the National Oceanic and Atmospheric Administration released a study which measured subsidence using leveling lines and GPS data on roadways, buildings, and other structures located in Louisiana, Mississippi, Alabama, Florida, Texas, and Ten-

Figure 3.3: The Lake Pontchartrain area served as a site for early fault related subsidence studies by Lopez et al. (1997). GNU Free Documentation Image License.

nessee (Shinkle and Dokka, 2004). Although this study did not explicitly study faulting, it has been the catalyst for subsequent research (Dokka et al. (2006); Dokka (2006)) on fault induced subsidence using similar methods. Figure 3.4 shows the locations of the first-order benchmarks that were used by Shinkle and Dokka (2004) to calculate subsidence. The “roadmap” likeness of this network (Shinkle and Dokka, 2004) is due to the benchmarks being placed along prominent highways and railways. These measurements were tied to the North American Vertical Datum of 1988 (NAVD 88).

A subsidence rate network was determined by comparing first-order leveling data on benchmarks during the past ~ 80 years. In southeastern Louisiana subsidence network values range from $0 - 25mm \cdot yr^{-1}$, with an average rate of $11mm \cdot yr^{-1}$. Figure 3.5 represents the measured subsidence rate on each benchmark by color, while figure 3.6 is a graphical representation of these values. According to the authors, “a great many assumptions, judgments, and choices went into assembling the network and computing the vertical displacement rates for each benchmark”.

Shinkle and Dokka (2004) assessed the validity of the subsidence network numbers by comparing them to information from tide records and continuously operated reference stations (CORS). Unfortunately, they found that no legitimate NAVD 88 elevation reference points were located across a substantial portion of the lower Mississippi Valley and that historical leveling data was unreliable for establishing current elevations. Because the previous elevation data was thought to be invalid, other surficial methods of determining subsidence were deemed useless. However, the authors propose that “ongoing vertical displacement must be monitored at a few fundamental locations and propagated through a base network using periodic reobservations” because elevations on benchmarks are not stationary. It was further concluded that be-

Estimates of Subsidence Rate throughout past 80 years

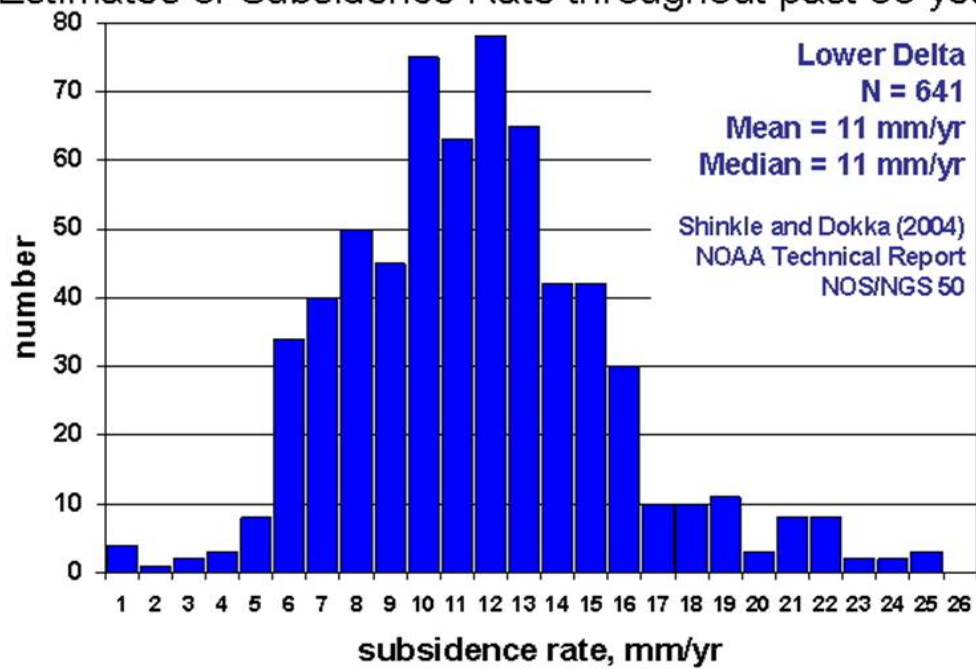

Figure 3.6: Graphical representation of subsidence rates measured from leveling data off first-order benchmarks.

Figure 3.7: Results from leveling data led Dokka to propose a slump block known as the South Louisiana Allochthon as the cause of fault-related subsidence in coastal areas (Dokka et al., 2006).

cause subsidence rates at individual points vary through time and over considerable spatial extents, vertical displacement rates may not change according to a linear function. Therefore, predictive models must take spatial and temporal rate variations into account (Shinkle and Dokka, 2004).

Shinkle and Dokka (2004) was followed by two similar studies, Dokka et al. (2006) and Dokka (2006). These two studies focused specifically on measuring subsidence from fault movement by expanding on the GPS data evaluated during the 2004 study. Dokka et al. (2006) applied GPS data obtained from 1995-2006 in order to evaluate subsidence from tectonic processes in the Mississippi Delta region. Both episodic observations (EGPS), which measures elevation changes over the course of a few days every one to two years, and continuously observed sites (CGPS), which constantly records elevation changes over 2-11 years, were used.

Individual faults along the coast are difficult to identify. Marshland, which is pervasive in many areas of southern Louisiana, masks clear surface expression of faults. This issue is reflected in the author's statement "proof that well-mapped subsurface faults are currently active and disrupt the surface is elusive" (Dokka et al., 2006). In light of this challenge, the Michoud fault system (located in close proximity to the northern margin of the Mississippi River at the northern structural edge of the basin), which had been identified and mapped using well cut-off and seismic reflection surveys (Hickey and Sabate (1972); McBride (1998)) was selected for study by Dokka et al. (2006).

Areas north and south of the Michoud and Teplatate-Baton Rouge fault system were measured using EGPS and CGPS on benchmark locations ranging from 14m to 30m deep rods to masonry buildings with stable foundations. This data was compared to previous leveling data (deemed invalid by the 2004 study) in the area. Results showed insignificant differential subsidence and

horizontal motion in sites north of the fault system; however areas to the south exhibited a subsidence rate of $5.2 \pm 0.9 \text{ mm} \cdot \text{yr}^{-1}$ and moved southward relative to North America at velocities of $2.2 \pm 0.6 \text{ mm} \cdot \text{yr}^{-1}$. Using this data, Dokka et al. (2006) suggested that southeast Louisiana is a regional coupled extensional-contractional complex with rates similar to the east-west extension of the contemporary central and eastern Basin and Range province. A large portion of southwestern Louisiana and the Gulf of Mexico, termed the South Louisiana allochthon (SLA), is thought to be detaching and moving south-southeast (Figure 3.7).

The second study (Dokka, 2006) looked at historical leveling data on benchmarks using the NAVD88 vertical datum. Once again using various benchmark locations near the Michoud Fault, velocities for years 1955 – 1969, 1969 – 1971, 1971 – 1977, 1977 – 1995, and 2005 were evaluated. Subsidence was broken into three categories: shallow, intermediate, and deep. The deep component, which specifically evaluated tectonism, was measured from the motions of benchmark BH1089, attached to a 2011 – *m* well. According to this study, subsidence rates from tectonic processes were $16.9 \text{ mm} \cdot \text{yr}^{-1}$ (1969 – 1971) and $7.1 \text{ mm} \cdot \text{yr}^{-1}$ (1971 – 1977), and accounted for 73% and 50% of the total subsidence measured during these time periods. It was suggested that these subsidence rates coincided with slip on the Michoud Fault, part of the proposed southern Louisiana allochthon, that occurred from 1969 – 1995.

Other efforts have been made to systematically evaluate the significance of fault-induced subsidence. Gagliano et al. (2003) used previously published maps, including Wallace (1966), Hickey and Sabate (1972), and available megaregional seismic cross sections from McBride (1998) and Strover et al. (2001) to identify 100 fault traces (Fig. 3.8) and create a regional structural framework for southeastern Louisiana. Figure 3.9 illustrates a cross section of the struc-

tural framework that was developed by overlaying surficial fault maps with mega-regional seismic lines.

Figure 3.8: Using maps and mega-regional seismic cross sections, Gagliano identified 100 fault traces making up the structural framework of Southeastern Louisiana. Gagliano et al. (2003)

Surface expressions of faults were identified using maps, aerial images, published descriptions, and personal interviews. This surface data was fitted to a north-south mega-regional cross section from McBride (1998), with a 61% correlation between surface faults and subsurface faults (Gagliano et al., 2003). The magnitude, rate of movement, and frequency of these faults were measured using maps, aerial imagery, geochronological data, tide gauge records,

Figure 3.9: Using surficial fault maps and mega-regional seismic lines, this structural framework cross-section was developed for Southeastern Louisiana. Gagliano (2005b)

and measurements from re-leveled benchmarks. Investigations done in six locations using vibracores and McCauley auger samples, were the basis of a north-south cross section (figure 3.10) created to quantify the effects of the Empire Fault, which was shown to have 3.5 ft of vertical displacement along the scarp (Gagliano et al., 2003). Similar works done on other faults in the area have recorded vertical displacements of up to five feet, which over a ~ 30 -year period is equivalent to $\sim 40\text{mm} \cdot \text{yr}^{-1}$ (Gagliano et al., 2003). As increased attention is placed on rehabilitating wetlands, it has been suggested that this method allows for effective assessment of fault process in order to adequately design coastal restoration projects (Gagliano et al., 2003).

3.3 Summary/Motivation

Vast areas of valuable wetlands have been lost, and this loss is projected to continue into the future. As models are being developed to curb coastal degradation, it is increasingly important to understand the processes that contribute to subsidence. The layers of complexity must be peeled back, and each individual component must be comprehensively evaluated. Faulting has been pervasive throughout the formation and development of the Gulf of Mexico. Movement of Jurassic-aged salt via continuous sediment loading has created a wide network of faults that are suspected to influence subsidence. While other drivers of subsidence have been proposed, understanding subsidence rates attributed wholly to geologic faults is imperative, as the current methodology used to evaluate subsidence from means such as shallow compaction or fluid removal inevitably measure total subsidence.

A barrage of data has been pieced together in an attempt to assess fault controlled subsidence. This work has primarily focused on using surface measurements, which in some instances, are loosely tied to a few seismic lines. Benchmark data, as well as the datum NAVD88 have not proven to be reliable means to detect fault movement; none-the-less, large-scale tectonic models have been created from leveled data. Previous work has relied heavily on personal opinion or conjecture. As more emphasis is placed on understanding how and why subsidence is happening, it is evident that a truly systematic method must be created to evaluate faulting process in the subsurface.

Chapter 4

Research Goal

Understanding the fault-controlled component of Mississippi River delta subsidence is critical to unraveling the complexity of coastal Louisiana's overall land-loss problem. Therefore, my work provides a refined method to measure local and sub-regional variations structural subsidence. Using modern 3-D seismic data, it is possible to provide exact representations of subsurface architecture (fault orientations, salt body locations, channels), as well as relative rates of displacement across individual faults. Local well control, combined with seismic imaging allows for better representation of long-term fault movement and sedimentation rates. Further, this work seeks to compare accurately mapped fault locations with contemporary orthophotos, in order to properly gauge effects on surface morphology.

Chapter 5

Methods

As previously stated, the goal of this project is to provide an unambiguous definition of both regional and counter-regional growth faults using 3-D seismic volume and complimentary well data. Measurements collected from the growth faults are then used to assess spatial and temporal variability in subsidence associated with structural deformation of delta-top deposits.

5.1 Seismic Data

The seismic volume utilized in this study is the multicient WesternGeco[®] Grand Lake/Black Bay/Quarantine Bay Emerge1 survey, covering a significant portion of western Breton Sound. The merged 3D survey consists of three individual 3D surveys shot between 1998 and 1999. Aerial extent of the $\sim 1400km^2$ survey is shown in figure 5.1. Its location is particularly relevant to this study because it encompasses an area that has experienced significant wetland loss during the past 80 years (Fig. 5.2). Because the area is a transition zone between land and shallow marine environments, both Opseis Eagle and Sercel 368 systems were used to record the data. A 3D Kirchhoff prestack time migra-

tion has been performed on the data to ensure optimal imaging of the complex subsurface structure. Table 5.1 provides a list of acquisition and processing parameters for the survey and its individual components.

2d/3dPAK is a fully integrated geophysical and geological interpretation software package for mapping horizons and faults using in-lines, cross-lines and arbitrary lines. VuPAK, an interactive 3D interpretation and visualization package, is completely integrated with TKS. Horizons and faults mapped out in TKS were imaged using VuPAK. All work was carried out on a DellTM Precision 690 workstation.

5.3 Attributes and Algorithms

Faults can be difficult to detect by using 3-D seismic amplitude data alone. Frequently they appear only as slight changes in the seismic waveform that can be challenging to correlate using traditional seismic cross-sections (Neves et al., 2004). To overcome this problem, I generated a seismic coherency volume from the original amplitude data using a second-generation, semblance-based coherency algorithm available via the OpendTectTM Software, an open-source seismic-processing code. After generating this volume it was loaded in the SMT seismic project for analysis along side the amplitude volume. With the co-

herency attribute volume, the fault locations could be mapped confidently, even in the shallowest interval of the data set. An attribute is simply any measure of seismic data that allows for better visualization of a particular feature (Neves et al., 2004), while an algorithm is the procedure for numerical manipulation of the data in order to achieve the desired attribute.

Seismic coherency is defined as a measure of lateral changes in the seismic response caused by variation in structure, stratigraphy, or other means (Marfurt et al., 1998). A coherence cube is effectively a cube of coherence coefficients produced from the input of a 3-D seismic data volume that exposes features such as faults and channels (Chopra, 2002). This method is superior to traditional shaded relief maps, which only permit 3D visualization of faults and channels based on horizon picks, because seismic coherency operates on the seismic data itself. Therefore, coherency is unfettered by interpreter or automatic picker biases (Marfurt et al., 1998). 3D coherency measurements evaluate trace-to-trace similarity. Because of this, seismic traces with sharp discontinuities, such as those offset by faults, result in low coherence along the fault plane, while continuous areas exhibit high coherence coefficients (Chopra, 2002).

The second-generation coherence algorithm, developed by Marfurt, uses semblance as a coherence estimate (Marfurt et al. (1998); Chopra (2002)). Semblance is defined as a quantitative measurement of the coherence of seismic data from multiple channels that is equal to the energy of a stacked trace divided by the energy of all the traces that make up the stack (Limited, 2008).

A coherency measurement is made by first defining a window of traces around each analysis point to be evaluated. This project defined a temporal analysis window of 56 traces, which is ideal for stacking the discontinuities related with vertical faults (Marfurt et al. (1998); Chopra (2002); Neves et al.

(2004)). Next, the semblance along a set of postulated planar reflectors was completed at a user selected maximum dip of $250\text{ms} \cdot \text{m}^{-1}$ and a delta dip of $10\text{ms} \cdot \text{m}^{-1}$.

Figure 5.3 (Marfurt et al., 1998), illustrates a typical calculation of coherency over an elliptical analysis window with arbitrary dips (q, p).

Figure 5.3: Typical coherency calculation over an analysis window using arbitrary dips (p, q). Modified after Marfurt et al. (1998)

5.4 Mapping

Proper assessment of subsidence and structure began with intensive mapping of horizons and faults using the 3-D seismic amplitude and coherency volumes.

5.4.1 Horizons

Roughly 15 horizons were mapped in the amplitude volume at depths between $\sim .450s$ and $\sim 1s$ TWT. Continuous, high-amplitude reflectors were selected as mappable horizons (figure 5.5), and the most laterally continuous horizon was selected as a proxy for total subsidence. Each of these horizons was mapped every 1 – 10 lines to ensure accurate tracking of the chosen reflector and accurate gridding of the interpreted horizon. Gridding a horizon simply implies that the horizon information has been interpolated to fill in an area between two known values.

The term “proxy subsidence” refers to a distinct horizon seen through out the seismic volume that is representative of total subsidence. As the horizon varies in the time domain, it can be thought of as varying in depth. Because deposition of a certain horizon would occur at time $t = 0$ (the surface), a “deeper” horizon would have a greater time and would therefore have undergone subsidence. It is important to note that this method shows total subsidence in time, but can be a helpful was to visualize subsidence patterns in areas of interest.

5.4.2 Faults

Determining the locations and offsets of faults were key elements of this study. Because faults can be difficult to map in amplitude data, all fault surfaces were mapped using the coherency volume. Incoherent data was assigned a dark color so that fault planes were easily recognized. Figure 5.6 displays three prominent faults imaged in both the amplitude and coherency volumes. Overall, 30 significant faults, both regional and counter-regional were identified in the survey.

Faults identified for thorough analysis were mapped every one to ten in-lines depending on the geometric complexity of the structure. After defining the fault plane this way, fault displacement was defined by measuring the off-

set of specific reflectors between the foot- and hanging-wall of the structure. These displacement measurements were collected on each line where the fault surface had been mapped. Roughly 5-10 measurements of reflector offsets were made per line, over a range of survey depths. Measurements of displacement associated with six individual faults is presented in the Data Analysis section and the appendix.

5.5 Well Control

Seismic data is collected in two-way time (TWT), so well data is necessary to develop an algorithm for converting TWT to burial depth and to provide age control for the mapped subsurface horizons.

5.5.1 Velocity Surveys

Correlated values of depth and time were obtained from check-shots in five well bores located within the bounds of the Grand Lake/Black Bay/Quarantine Bay survey. Well information and location for the five velocity surveys is listed in Table 5.2.

A velocity survey allows for an independent assessment of time versus depth, yielding both average and interval velocity measurements (Dobrin and Savit (1988); Limited (2008)). Using geophones, lowered to a number of known depths in the well-bore, the arrival times of waves generated by a charge, vibrosies unit, or air-gun array (used in marine areas) are recorded. Interval velocities, such as those used in this survey, are acquired by dividing the distance between consecutive geophone positions in the well-bore by the difference in arrival times recorded at the two depths after the arrival times are corrected for wave path angularity (Dobrin and Savit, 1988). Average velocities were not used in this study.

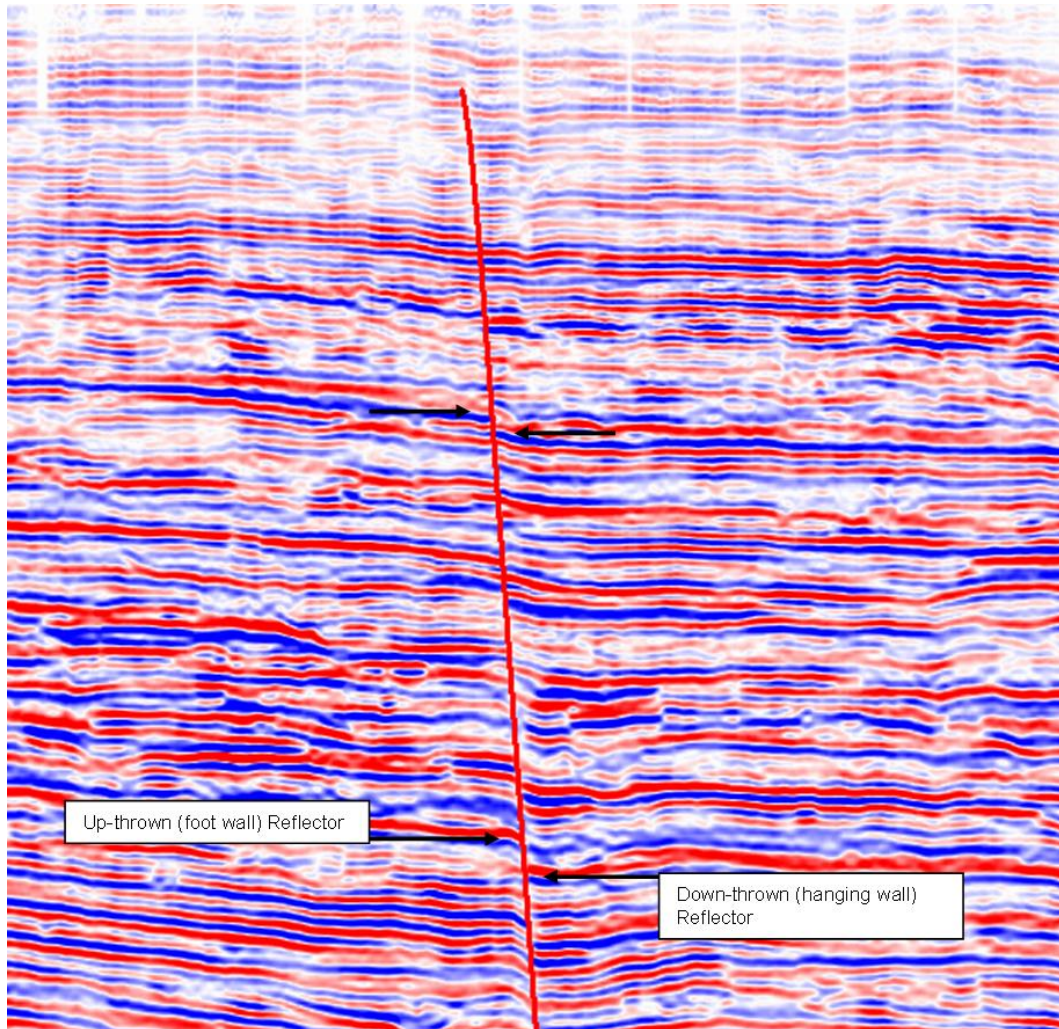

Figure 5.4: Fault displacement was defined by measuring the offset of specific reflectors between the foot- and hanging-wall of the structure.

Figure 5.5: A horizon (in cyan), used to determine proxy subsidence, was mapped throughout the survey on a continuous peak reflector.

Figure 5.6: Faults imaged in amplitude (top) and coherency (bottom). Using coherency, discontinuous areas offset by faults have much better resolution which is useful for detailed mapping in shallow parts of the 3D volume.

API Number	Well Name and Well Number	Lambert Coordinates	Measured Depth (m)

Table 5.2: Velocity surveys from five wells located within the 3D survey were incorporated to convert time (*s*) to depth (*m*).

Time versus depth data for the five wells is plotted in Figure 5.7. The best-fit polynomial to this data was used to convert measurement of time into values of burial depth for the 3-D seismic volumes.

The acoustic velocity associated with deposits at specific burial depths was calculated using the time and depth data shown in the upper graph of Figure 5.7. These interval velocities are shown in the lower graph of Figure 5.7, systematically increasing with increasing burial depth.

5.6 Mississippi Surface Data

In order to evaluate the effects of fault-induced subsidence on morphology of the delta surface, I compared high-resolution surface data against the mapped positions of growth faults.

Figure 5.7: Time vs. Depth and interval velocity for wells in 3D-survey

5.6.1 Digital Orthophoto Quarter Quadrangles

Louisiana State University offers hundreds of high resolution Digital Orthophoto Quarter Quadrangles (DOQQ). These images, taken from flyovers and recorded using infrared light, cover an area of about $46km^2$, each pixel representing about one meter. Also, DOQQ photos are georeferenced, meaning they are registered to specific locations on Earth's surface and compatible with other scaled maps. This study used 44 orthophoto quads taken in and around Breton Sound during 2005. All 44 photos were assembled using Adobe Photoshop[®] to create a large image covering the study area. Surface features displayed on this aerial image were compared to fault structures resolved by high-resolution 3-D seismic time slices (made at $.450s$ and $1s$) to obtain a true sense of how faulting influences contemporary delta-top morphology

Chapter 6

Data Analysis

The methods used to evaluate fault induced subsidence have created a completely new suite of information concerning structural complexity, variation in subsidence rates, fault-slip rates, and delta-surface morphology in southeastern Louisiana.

6.1 Structural Analysis

Extensive mapping identified 30 substantial growth faults in the survey area. Of these faults, 24 are regionally oriented (hanging wall down-to-the-basin, south) and the remaining six are counter-regional (hanging wall down to the north) in nature. Figures 6.1 & 6.2 are base maps which show the locations of each fault visible on .450s and 1s coherency time slices. Regional faults are signified on the map in red and counter-regional faults are colored green. Continuous lines indicate a clearly traceable fault, while the dashed lines represent areas of inferred faulting. Faults range in length from .2 km to more than 15 km, and the majority of faults are located in the eastern section of the survey.

Most faults can be mapped to shallow depths that are limited by the seismic resolution ($\sim .300s$) and extend to depths greater than $\sim 1.5s$.

At $t = 1s$, the coherency time slice reveals many clearly defined faults and channels. At $t = .450s$, faults are still clearly visible, however their lateral extents are reduced due to the shallowness of the slice, combined with the listric nature of growth faulting. Collection cones (seen as dots on the surface) are seismic artifacts associated with this shallow map. It is important to note that the cones do not affect the resolution of the faults.

Mapping efforts also revealed a large salt body related to the Jurassic-aged Louann salt. Sediment loading, combined with this salt movement has created the long, complex fault system in the southernmost portion of the survey area. The stratigraphy around the salt body has been dramatically altered. Large mini-basins, known to be areas of hyper-subsidence, are readily seen in conjunction with the mobile salt under the Mississippi River. Because faulting was most intense around salt-structures, it is suspected that these fault networks are induced due to factors related to salt evacuation.

Intertwined counter-regional and regional faults are seen around the salt structure in the southern portion of the survey, which subsequently influence the planform of the Mississippi River near the Jackson Bend. To the west, away from the salt, a stark reduction in frequency of faulting is seen. In that area, one fault (and a small portion of another fault extending from the west) is mappable in shallow substrate. This regional growth fault also interacts with the Mississippi River near a separate bend.

The structural complexity seen in the dataset ($\sim 1400km^2$) appears to be more influenced by localized factors such as salt body movement and sediment loading. No evidence was seen to suggest large-scale tectonic influences such as the proposed SLA (Dokka, 2006).

Figure 6.1: Substantial faults mapped in .450s coherency time slice. Red lines indicate regional growth faulting, green lines indicate counter-regional growth faulting.

Figure 6.2: Substantial faults mapped in 1s coherency time slice. Red lines indicate regional growth faulting, green lines indicate counter-regional growth faulting.

6.2 Proxy Subsidence Map

The pattern of Quaternary subsidence in the survey area has been established through the mapping of a particularly continuous reflector through out most of the 3D survey. Vertical position of this reflector ranged from $.354s$ to $.738s$, depending on location. After fully mapping the reflector, the resulting horizon was gridded so that a time value for the horizon was assigned to each grid point in the survey. Using the velocity survey from LA State 3381, the gridded horizon was converted from time to burial depth (figure 6.3). Since local and regional relief of the delta top is very small, less than $8m$, this map defines the pattern of variable subsidence in the study area.

Expectedly, these map in Figure 6.3 displays an overall increasing subsidence to the south, towards the center of the GOM basin. However, subsidence is locally greatest in those areas exhibiting faulting, especially around the salt structure. A zone of high subsidence parallels the large counter-regional fault in the south, which also coincides with position of the Mississippi River. The proxy subsidence map records the total subsidence acting upon a horizon, and clearly demonstrates that faults influence local subsidence patterns within the bounds of this 3D-survey.

6.3 Individual Fault Measurements

Numerical values of fault movement through time were collected for six select faults. Fault movement is an important component of overall subsidence because a growth fault creates focused accommodation space on the downthrown side of the fault. A description of all 6 faults is presented below. The appendix lists all measurements made above $\sim 1500ft$ on each fault.

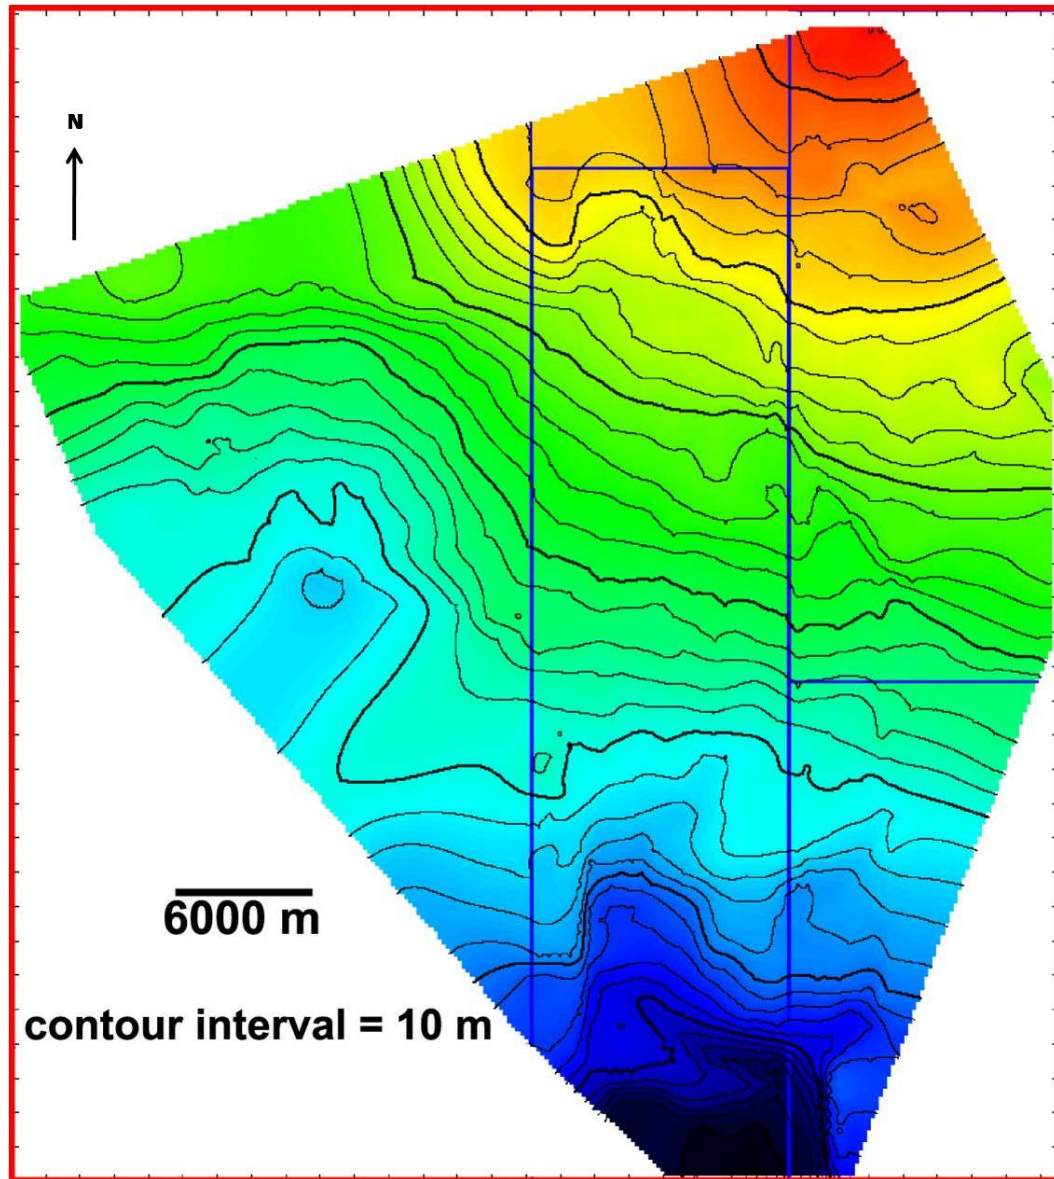

Figure 6.3: Proxy subsidence map converted from time to depth. Higher subsidence areas are shown in cool colors. The “arm” of high subsidence located in the south corresponds to the location of a network of salt-induced growth faults, which also appear to influence the plan-form of the Mississippi River.

6.3.1 Regional Growth Fault “A”

Fault “A” is located between Lambert Coordinates $X : 2553491.3$, $Y : 248536.3$ (western extent) and $X : 2602081.6$, $Y : 262577.3$ (eastern extent) in the southern portion of the survey. This fault is a $\sim 10km$ long, regional growth fault oriented NE-SW and dipping to the S-SE.

Figure 6.4 shows data collected from this fault. The upper graph illustrates fault offset (m) versus depth below delta surface (m), while the lower graph shows the fault offset ratio (local value for fault displacement to burial depth) also plotted against depth below delta surface (m). Maximum fault offset is $120m$ at a depth of $\sim 1300m$, however most offsets range from zero to $\sim 60m$. The wide range in measured values for displacement represents behavior for the entire fault. Displacement values are small near the fault tips where displacement must go to zero. The maximum values for the offset ratio increase with burial depth from roughly 6% at shallowest depths to 9% at greater depths. This means that while total accumulated displacement across this fault is systematically increasing over geologic time, the degree of displacement on this fault is decreasing through geologic time. For example, at $300m$ the maximum fault offset is $18m$ (6% of the depth), while at $900m$ fault offset is 7.5% of the depth or $67.5m$.

6.3.2 Regional Growth Fault “B”

Fault “B” is located between Lambert Coordinates $X : 2562308.9$, $Y : 349699.9$ (western extent) and $X : 25999096.9$, $Y : 335641.8$ (eastern extent) in the east central portion of the survey. This fault is a $\sim 12km$ long, regional growth fault oriented NW-SE and dipping to the S-SW. Data for this fault is seen in figure 6.5.

Figure 6.4: Data collected for regional fault “A” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases roughly linearly with depth below the delta surface. Maximum fault offset is $\sim 120m$, however most faults range from 0 – 60m of offset on a reflector. The offset ratios (the measured fault offset divided by depth below the delta surface) range from 6 – 9% of the depth below the delta surface, increasing with depth.

Maximum measured displacement on this fault does not exceed $\sim 50m$ and the maximum values for offset ratio remain a constant 5% with depth below the delta surface. This means that the degree of displacement on this fault is remaining constant over time.

6.3.3 Regional Growth Fault “C”

Fault “C” is located between Lambert Coordinates $X : 2543286.2$, $Y : 362765.2$ (western extent) and $X : 2574540.8$, $Y : 364118.2$ (eastern extent) in the northern portion of the survey. This fault is a $\sim 10km$ long, regional growth fault oriented E-W and dipping to the south.

Values obtained from measuring this fault are presented in figure 6.6. The maximum measured offset on this fault is about ($60m$) and maximum offset ratio remains a constant 5.5% with depth below delta surface.

6.3.4 Regional Growth Fault “D”

Fault “D” is located between Lambert Coordinates $X : 2539317.8$, $Y : 26569.4$ (western extent) to $X : 2561092.0$, $Y : 254476.4$ (eastern extent) in the southern portion of the survey. This fault is a $\sim 8km$ long, regional growth fault oriented NW-SE and dipping to the S-SW.

Figure 6.7 shows that this fault has a maximum offset of $110m$ at $\sim 1300m$ below the delta top, and that maximum values for the offset ratio values increase from 5.5% to 8% with depths from zero to 1500 m below delta surface.

6.3.5 Regional Growth Fault “E”

Fault “E” is located between Lambert Coordinates $X : 2478851.8$, $Y : 324719.7$ (western extent) and $X : 2495551.6$, $Y : 323357.1$ (eastern extent) in the western

Figure 6.5: Data collected for regional fault “B” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases roughly linearly with depth below the delta surface. Faults range from 0 – 50m of offset on an n individual reflector.

The offset ratios (the measured fault offset divided by depth below the delta surface) holds constant at approximately 5% of the depth below the delta surface.

Figure 6.6: Data collected for regional fault “C” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases roughly linearly with depth below the delta surface. Maximum fault offset is $\sim 120m$, however most faults range from 0 – 60m of offset on a reflector.

The offset ratio (the measured fault offset divided by depth below the delta surface) is consistently 5.5% of the depth below the delta surface.

Figure 6.7: Data collected for regional fault “D” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases roughly linearly with depth below the delta surface. Maximum fault offset is $\sim 110m$ on an individual reflector.

The offset ratios (the measured fault offset divided by depth below the delta surface) range from 5.5 – 8% of the depth below the delta surface, increasing with depth.

portion of the survey. This fault is a $\sim 3km$ long, regional growth fault oriented E-W and dipping to the south.

Measurements made of this fault are summarized in figure 6.8, which shows offsets ranging from zero to $\sim 100m$ and a constant maximum offset ratio of 8%.

6.3.6 Counter-Regional Growth Fault “F”

Fault “F” is located between Lambert Coordinates $X : 2552857.3, Y : 264445.8$ (western extent) and $X : 2588735.9, Y : 25437.6$ (eastern extent) in the southern portion of the survey. This fault is a $\sim 12km$ long, counter-regional, salt induced growth fault oriented in an arcing E-W orientation and dipping to the north.

Figure 6.9 shows that this fault has the highest maximum displacement of any fault measured with a value of $\sim 150m$. The maximum values for the offset ratio increase from about 4 to 11% with burial depth. This means that the degree of displacement on this fault is decreasing somewhat over geologic time.

6.4 Estimate of Faulting-Induced Subsidence

The lack of significant reduction in offset ratio through time for the studied growth faults (Figs. 6.4 to 6.9) suggests that these structures are active today. If active, these faults should be producing enhanced or extra subsidence associated with displacements of their hanging walls. I can estimate the magnitude of this enhanced subsidence by combining the near-surface values of fault offset ratio with appropriate measures of deposition rate to calculate a fault-related subsidence rate (FSR), where $FSR = \frac{\text{fault displacement}}{\text{subsurface depth}} \times \frac{\text{depositional thickness}}{\text{time}}$. The near-surface values of offset ratio $\left(\frac{\text{fault displacement}}{\text{subsurface depth}} \right)$ for the six studied faults

Figure 6.8: Data collected for regional fault “E” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases roughly linearly with depth below the delta surface. Maximum fault offset is $\sim 110m$, however most faults range from 0 – 100m of offset on a reflector. The offset ratio (the measured fault offset divided by depth below the delta surface) is 8% of depth below the delta surface.

Figure 6.9: Data collected for counter-regional fault “F” shows fault offset (upper graph) and the fault offset ratio (lower graph) plotted against the depth below the delta surface. In this data set, fault offset increases exponentially with depth below the delta surface. Maximum fault offset is $\sim 150m$. The offset ratios (the measured fault offset divided by depth below the delta surface) range from 4 – 11% of the depth below the delta surface, increasing with depth.

are straightforward to measure (Figs. 6.4 to 6.9) and range between 0.039 and 0.080, with a mean of 0.056.

Generating appropriate values for deposition or burial rate is a little more involved. I assume that deposition rates are roughly equal to the sum of space created by eustatic sea-level rise and land-surface subsidence (Paola, 2000). Based on the tide-gauge record at Pensacola, FL, present-day eustatic sea-level rise is assigned a rate of $2.1\text{mm} \cdot \text{yr}^{-1}$ (González and Törnqvist, 2006). The mean value for millennial-scale subsidence rates reported by Morton et al. (2005) and Meckel et al. (2006) is $1.4\text{mm} \cdot \text{yr}^{-1}$ ($n = 104$) and the mean value for decadal-scale subsidence rates reported by Shinkle and Dokka (2004) is $11\text{mm} \cdot \text{yr}^{-1}$ ($n = 641$). Summing the sea-level rise and subsidence rates yields high and low estimates for deposition rate of $13\text{mm} \cdot \text{yr}^{-1}$ and $3.5\text{mm} \cdot \text{yr}^{-1}$. These rates, together with our measurements of offset ratio define the range of calculated values for FSR presented in Table 6.1.

Calculated values of vertical displacement rate for the studied growth faults (Table 6.1) are consistent with measurements previously reported by Lopez et al. (1997). Our calculated values for displacement over decadal to millennial time intervals are less than the annual faulting rates of $2.5\text{mm} \cdot \text{yr}^{-1}$ to $10\text{mm} \cdot \text{yr}^{-1}$ and are greater than the very-long term (1,000,000+ years) rates that range between $0.003\text{mm} \cdot \text{yr}^{-1}$ and $0.064\text{mm} \cdot \text{yr}^{-1}$ (Lopez et al., 1997), which likely includes times of quiescence and movement.

In addition to calculating decadal and millennial time-scale fault displacement values, longer-term movement values for the entire Holocene (11,550 *years*) were calculated using long-term deposition rates reported by Stanley et al. (1996). The fault-related subsidence rate (FSR) is equal to the offset ratio times the deposition rate. Dividing these thicknesses by the time duration for the

Holocene yields minimum and maximum deposition rates averaged over the past 11,500 years of $1.7\text{mm} \cdot \text{yr}^{-1}$ and $6.8\text{mm} \cdot \text{yr}^{-1}$.

By multiplying upper, lower, and mean offset ratios by the depositional rates, long-term fault displacement versus time values were calculated. Table 6.1 lists the various calculations. The rates of displacement, which are a proxy for fault induced subsidence, range from $0.07\text{mm} \cdot \text{yr}^{-1}$ to $0.14\text{mm} \cdot \text{yr}^{-1}$ (lower limit of sedimentation times lower to upper limit of fault offset ratios) to $0.27\text{mm} \cdot \text{yr}^{-1}$ to $0.55\text{mm} \cdot \text{yr}^{-1}$ (upper limit of sedimentation times lower to upper limit of fault offset ratios). These values are much lower than values obtained from studies employing surface-based fault measurements, and suggest those measurements are recording other subsidence drivers in addition to fault movement.

Both recent and long-term fault movement values suggest that displacements of active geologic faults in greater Breton Sound, Louisiana are on the order of less than $1\text{mm} \cdot \text{yr}^{-1}$. These numbers are in direct contrast to higher values, measured via surface or very shallow substrate methods, which suggest that fault movement ranges between $\sim 7.0\text{mm} \cdot \text{yr}^{-1}$ to $\sim 17.0\text{mm} \cdot \text{yr}^{-1}$ (Dokka et al., 2006) and $\sim 36\text{mm} \cdot \text{yr}^{-1}$ (Gagliano et al., 2003).

6.5 Surface Data Comparison

Faults mapped on coherency time slices were co-registered with digital orthophoto quads of the delta top in order to determine if the identified growth faults were influencing the modern-day surface morphology. In keeping with previous figures, red lines indicate regional growth faults, while green lines signify counter-regional faulting. Solid lines represent mapped fault traces and dashed lines define the inferred positioning of faults.

Figures 6.10a & 6.10b, shows the positioning of regional growth fault “C”, located in the northern portion of the survey. The hanging wall for this normal fault, a potential site of enhanced subsidence, is on the southern side of its fault trace. There is a remarkable correlation between the exposure of Bayou Lery to the open water of Black Bay and the position of this growth fault. The fault location strongly corresponds with the southern extent of the wetland and cutting of the Lery channel margin. This correlation improves as the burial depth associated with the co-registered fault trace decreases from 1s to .450s TWT. The drowned areas of marshland south of the fault trace suggest that the extra subsidence associated with an active hanging wall is sufficient to promote wetland inundation.

Regional growth fault “E”, seen in figures 6.11a and 6.11b, is located in the western portion of the survey at Socola, LA. The fault trace defines a boundary between inundated wetlands and the distal Mississippi River levee to the south and relatively emergent topography to the north. There is no obvious topographic expression of the fault on the proximal river levee, suggesting that sites prone to active river sedimentation can overcome the enhanced subsidence associated with the growth faulting or that engineering practices on the proximal levee have masked the fault/surface-morphology interaction. Note that as subsurface depth decreases, the correspondence between fault location and the surface morphology strengthens (6.11b). Inferred faulting areas (dashed lines) are due to gaps in the shallow portions of the seismic. The presence of a discrete fault is suspected in this area, and strong fault signals are observed either side, however because of data gaps this portion must be inferred at 1s TWT (no fault evidence is seen at .450s TWT).

Figures 6.12a and 6.12b show regional fault “D” and a small segment of counter-regional fault “F”, located near the Mississippi River in the southern

portion of the survey. This fault is also oriented with southerly directed fault movement, and like previous faults, the position of the structure suggests an influence of surface morphology. To the east, a canal seemingly is taking advantage of the fault location. Moving westward, the southerly extent of the wetland also appears to be influence by fault position, a correlation that improves as time decreases. The 3-D seismic coverage does not extend into the far West portion of the orthophoto, but the surface morphology of the wetland suggests some growth fault influence.

On the west side of the photo panel, a wetland is positioned between green counter-regional fault “F” and red regional fault “A”. Because these faults are slipping in opposite directions, a high, which directly corresponds to the location of the wetland, is created. Inferred faulting is once again used here because of data gaps over the Mississippi River in the shallow portion of the seismic.

An unnamed regional growth fault and a small piece of counter-regional fault “F” in Breton Sound are seen in Fig. 6.13. These pictures also show a notable connection between the emergent wetland on the footwall and open water over the hanging wall. Notice that crevasse splays of the Mississippi River are actively filling in the space created by hanging-wall subsidence.

A more complex system of faults related to salt movement is seen in Figs. 6.14a & 6.14b, along the Mississippi River. Both regional and counter-regional faults intertwine, creating various overprints on the surrounding morphology. To the east, fault “A” crosses the river and then strongly mimics the curves of the Jackson Bend, further suggesting that faults influence various types of surface processes seen in southeastern Louisiana, including the planform of the Mississippi River itself.

(a) 1.0s fault trace, in red, layered over an orthophoto. The location of the fault closely corresponds to the southerly extent of the marsh.

(b) .450s fault trace in red, layered over an orthophoto. Due to the shallow depth of the coherency data and the listic shape of the fault, the fault trace location better correlates to the edge of the wetland than the 1.0s trace.

Figure 6.10: Orthophoto Panel 1

(a) 1.0s fault trace, in red, layered over an orthophoto. The location of the fault closely corresponds to the southerly extent of the marsh. Fault is suspected to continue to the West, however no seismic data was available to confirm this.

(b) .450s fault trace in red, layered over an orthophoto. Due to the shallow depth of the coherency data and the listic shape of the fault, the fault trace location better correlates to the edge of the wetland than the 1.0s trace.

Figure 6.11: Orthophoto Panel 2

(a) 1.0s regional fault trace, in red, and counter-regional fault trace, in green, layered over an orthophoto. The faults seen here closely mimic the spatial extents of several wetlands. Although lack of seismic coverage to the west limits the traceability of fault signatures, it is suspected that fault influence on wetlands continues on west-ward.

(b) .450s regional fault trace, in red, and counter-regional fault trace, in green, layered over an orthophoto. The faults seen here closely mimic the spatial extents of several wetlands. Although lack of seismic coverage to the west limits the traceability of fault signatures, it is suspected that fault influence on wetlands continues on west-ward.

Figure 6.12: Orthophoto Panel 3

(a) 1.0s regional fault trace, in red, and counter-regional fault trace, in green, layered over an orthophoto. The locations of the faults roughly correspond to the location of the wetlands. Note crevasse splays filling space created by the hanging wall subsidence.

(b) .450s fault trace in red, and counter-regional fault trace, in green, layered over an orthophoto. Due to the shallow depth of the coherency data and the listric shape of the fault, the fault trace location better correlates to the location of the wetland.

Figure 6.13: Orthophoto Panel 4

(a) 1.0s regional fault trace, in red, and counter-regional fault trace, in green, layered over an orthophoto. This network of complex faulting is associated with mobile salt, and the resultant fault pattern corresponds to the location of wetlands and the plan form of the Mississippi River.

(b) .450s fault trace in red, and counter-regional fault trace, in green, layered over an orthophoto. Due to the shallow depth of the coherency data and the listic shape of the fault, the fault trace location better correlates to the locations of the wetlands and to the plan form of the Mississippi River.

Figure 6.14: Orthophoto Panel 5

	Offset Ratio	Dep. Rate ($mm \cdot yr^{-1}$)	F.S.R. ($mm \cdot yr^{-1}$)
Minimum offset \times millennial deposition rate	0.039	3.5	0.14
Mean offset \times millennial deposition rate	0.056		0.20
Maximum offset \times millennial deposition rate	0.080		0.28
Minimum offset \times decadal deposition rate	0.039	13	0.51
Mean offset \times decadal deposition rate	0.056		0.74
Maximum offset \times decadal deposition rate	0.080		1.0
Minimum offset \times minimum Holocene deposition rate	0.039	1.7	0.07
Mean offset \times minimum Holocene deposition rate	0.056		0.10
Maximum offset \times minimum Holocene deposition rate	0.080		0.14
Minimum offset \times maximum Holocene deposition rate	0.039	6.8	0.27
Mean offset \times maximum Holocene deposition rate	0.056		0.38
Maximum offset \times maximum Holocene deposition rate	0.080		0.55

Table 6.1: Calculated values of fault-related subsidence rates, $FSR = \frac{\text{fault displacement}}{\text{subsurface depth}} \times \frac{\text{depositional thickness}}{\text{time}}$. These rates characterize the magnitude of enhance subsidence associated with the vertical displacement for hanging walls of growth faults.

Chapter 7

Interpretation of Results

The information obtained using industry quality 3-D seismic, well control, high-resolution aerial imagery, and previously published depositional rates provide new insight into fault related subsidence rates and patterns. Additionally, this study confirms a significant influence of growth faulting on the modern-day surface morphology of southeastern Louisiana. However, the magnitude of fault movement and the mechanisms by which movement occurs are different than those previously proposed by other workers.

7.1 Rates of Fault Movement

The new data presented in this study provide differing results in comparison to traditional views on fault-related subsidence in coastal Louisiana. Earlier studies have recorded vertical displacement rates for faults ranging from $\sim 2.5\text{mm} \cdot \text{yr}^{-1}$ (Lopez et al. (1997)) to $\sim 16\text{mm} \cdot \text{yr}^{-1}$ (Dokka (2006)). However, long-term fault displacement rates, observed from detailed subsurface analysis of 3-D seismic data and well control, are on the order of $< 1\text{mm} \cdot \text{yr}^{-1}$, even at the upper-most limit observed (high offset ratio from salt movement combined

with high sedimentation). This discrepancy in values suggests that higher displacement rates proposed by surface mapping of faults are not representative of typical fault movement through time.

Although higher rates could be transient rates (which only occur for a short time and whose origins are not fully understood), it is likely that these high values occur because measurements made at the surface or in shallow substrate measure total subsidence, not just fault-related subsidence. Therefore rates are overprinted by other subsidence drivers such as natural compaction or fluid removal . Also contributing to higher rates are measurements skewed by on-going surficial processes such as current and wave reworking. As a wetland is converted to open water, it is quickly exposed to high energy waves which can erode the surface. This erosion can easily be mistaken for subsidence and the offset created by erosive processes incorporated into a subsidence measurement. Increased weight from man-made infrastructure such as roadways, railroads, and structures can further augment the appearance of high subsidence which can be overprinted on surface measurements. All of these scenarios occur in southeastern Louisiana and may be influencing previous attempts to quantify fault-induced subsidence.

7.2 Mechanisms of Fault Movement

This study not only challenges prior understanding of subsidence rates, but also the mechanisms by which fault movement occurs. Past workers have described fault movement as originating from the southerly movement of the SLA (Dokka (2006); Dokka et al. (2006)). This structure is suggested to be extending at rates comparable to the Basin-and-Range Province of the western United States, however concentrated mapping of the subsurface using both 3-D seismic

amplitudes and related attributes has uncovered that faulting around Breton Sound occurs at a much more local level.

Faults appear to have varying character depending upon rates of deposition (sediment loading) and proximity to mobile salt bodies. More intense faulting occurs near salt bodies, while away from the salt, sediment loading appears to be driving fault movement. No faulting patterns consistent with occurrence of the SLA were observed in roughly 1400km^2 of 3-D seismic coverage situated within the proposed allocthon. Additionally, a proxy subsidence map generated from a continuous horizon illustrates that salt related faulting dramatically influences regional subsidence patterns through the creation of zones of enhanced subsidence above the hanging walls of both regional and counter-regional growth faults.

7.3 Fault Control on Surface Morphology

When overlain with digital orthophotos, the coherency time slices reveal the control of growth faults on the spatial extents of marshland. Wetlands are found capping the footwalls of many growth faults, while the down-thrown hanging-walls are drowned. The low rate of measured long-term fault displacement suggests that only relatively small additional subsidence along faults is necessary to convert marshland to open water.

Two bends of the lower Mississippi River are also influenced by faulting. As seen in the digital orthophoto quads, the arc-like shape of the salt derived faults set the character of the Jackson bend.

Chapter 8

Conclusions

Recent catastrophic events such as Hurricane Katrina have renewed attention to an on going debate concerning the fundamental drivers of subsidence in coastal Louisiana. As large areas of wetlands and barrier islands (imperative for protection against storm surges) are lost, many scientists are developing predictive models for coastal restoration. However, because the northern Gulf of Mexico basin has experienced not only a complex geologic history, but the compounded effects of human influence, drivers of subsidence are numerous and poorly understood. To achieve optimum results from rehabilitation efforts, each proposed subsidence driver must be independently evaluated and quantified. Subsidence related to fault movement is a critical component of that issue.

In an effort to compute fault induced subsidence rates, previous studies have heavily relied on surface measurements from benchmarks and other man-made structures. That strategy has resulted in extremely high subsidence values which have been recorded at upwards of tens of millimeters of movement per year. Those values have been used to suggest large-scale tectonic models such as the South Louisiana allochthon (SLA). I have shown that

past approaches do not adequately address subsidence rates attributed wholly to geologic faults, but rather further complicate understanding of Louisiana's subsidence problem.

Using modern subsurface technology including $\sim 1400km^2$ of 3D Kirchhoff PSTM seismic data, a second-generation coherency algorithm, and several velocity surveys from borehole check-shots, this study challenges traditional thinking about fault related subsidence. Rates of subsidence obtained from true subsurface mapping and measurement are significantly less than rates derived from surface mapping and measurements, proving that subsurface mapping and measurement is vital for obtaining realistic values and understanding of subsurface processes. This work has effectively shown that incomplete data lead to a skewed understanding of fault induced subsidence.

Problems arise when relying only on surface measurements to understand faulting, because surface measurements often record total subsidence from all contributing drivers (natural compaction, fluid removal). Additionally, surface measurements can be altered because there are surface processes at work which are independent of faulting. As land drowns, it is subjected to reworking from currents and waves, which gives the appearance that the fault has moved upwards of several centimeters to roughly a meter in a short time, when actually the fault has moved perhaps a few millimeters. Furthermore, when using man-made structures such as railroads or highways, compaction from the devices using that infrastructure undoubtedly distorts measured values. It is nearly impossible to make claims and generate values of movement related to subsurface features using only surface data, which has been influenced by surface processes. These exaggerated fault movement (subsidence) rates have created a "sky is falling" attitude about mitigation of coastal land loss.

True subsurface measurements of six faults, both regionally and counter-regionally oriented, have revealed that fault movements in a typical coastal land loss area are on the order of $0.1-1mm \cdot yr^{-1}$. By multiplying $\frac{\text{fault displacement}}{\text{subsurface depth}} \times \frac{\text{depositional thickness}}{\text{time}}$ a fault related subsidence rate (FSR) was calculated for decadal and millennial time scales, as well as the entire Holocene (11,500 years). These rates (described in Table 6.1) provide minimum and maximum FSRs based on possible differences in sedimentation and fault severity. Based on those values, a minimum decadal $FSR = .51mm \cdot yr^{-1}$, an average decadal $FSR = .74mm \cdot yr^{-1}$, and a maximum decadal $FSR = 1.0mm \cdot yr^{-1}$ was calculated. For the minimum millennial time scale $FSR = .14mm \cdot yr^{-1}$, the average $FSR = .20mm \cdot yr^{-1}$, and the maximum millennial $FSR = .28mm \cdot yr^{-1}$. Finally, the Holocene minimum $FSR = .07mm \cdot yr^{-1}$, the average Holocene $FSR = .24mm \cdot yr^{-1}$, and the maximum $FSR = .55mm \cdot yr^{-1}$. These rates are much lower than most previous fault-related subsidence rates acquired by surface or shallow substrate methods, with the exception of values obtained by Lopez et al. (1997). These values further suggest that faulting is the result of localized influences such as salt evacuation and sediment loading, rather than large-scale tectonic models such as those proposed by Dokka (2006).

Although these fault movements are less than previously suspected, they can impact wetland morphology, as seen in the digital orthophotos. Using high resolution digital orthophoto data, coupled with seismically mapped fault traces, I have effectively shown that fault locations closely correspond with the spatial extent of wetlands and of the plan-form of the Mississippi River at the Jackson Bend.

This study has effectively proposed a systematic approach to evaluation of fault induced subsidence, which completely changes the context for examining faults. Once treated as evidence of mega-regional blocks, faults must now be

considered individually because of local influences such as salt which can alter fault character. Any engineering project aiming to rehabilitate wetlands must take each fault into consideration. One-size-fits-all methods of subsidence evaluation are inadequate to properly address the subsidence problem in southern Louisiana. However, by inputting correct values for subsidence into promising costal wetland rehabilitation models, better efforts can be made to refurbish Louisiana's dwindling marshlands. With more innovative approaches to assessing subsidence from all possible drivers, both at the surface and in the subsurface, legitimate progress can be made to mitigate coastal land loss and re-establish protection of Louisiana's population and commerce.

Vita

Terra Jane George, daughter of Terry Lee and Kathy Lee George, was born on March 20, 1983 in Okmulgee, Oklahoma. Upon receipt of her diploma in 2001 from Morris High School, in Morris, Oklahoma, she entered Oklahoma State University in Stillwater, Oklahoma. While at Oklahoma State, she held internship positions with the Natural Resources Conservation Service, Lamamco Drilling Company, and Chesapeake Energy Corporation, and in May 2006, she completed a Bachelor of Science in Geology. In August 2006, she entered the Jackson School of Geosciences at University of Texas at Austin to pursue a Master of Science in Geosciences. She also held an internship position with ConocoPhillips Co. in Summer 2007.
